

Multi-Lane Automated Intersection Management

Edward Lambert

November 5, 2021

1 Introduction

In previous chapters the throughput and delay of a number of promising Automated Intersection Management (AIM) algorithms have been compared on two perpendicular lane segments which meet in the middle. This might be called an elementary intersection. There are certain traffic phenomena which are difficult or impossible to observe in this environment, so it is difficult to draw firm conclusions about the superiority of one method. For instance, larger intersections will often permit non-conflicting flows such as opposing left turns (for those driving on the left-hand side).

The wider motion coordination problem faced by fleets of identical material transfer AGVs is described in Problem 1. A convenient representation of the workspace W is a connected graph of waypoint paths which avoid the static obstacles in the environment. This includes the starting position of every AGV $\tau_i(0)$, and the mission locations M_j .

Problem 1 Given a number N AGV operating in a workspace $W \in R^2$, what trajectory $\tau_i(t) \in W$ should each one follow to complete all missions in the minimum total AGV-Time. A mission takes place at position $M_j \in W$. A collision-free distance $\|\tau_i(t) - \tau_k(t)\| > d_{min}$ must be maintained between each AGV at all times.

Numerous ways of dividing and conquering this problem have been developed. One of the most common is the conflict-free routing approach, where the path is discretized and segments are assigned to one vehicle at a time [?]. This can be solved by sequentially finding the shortest path through a Space-Time-Extended Network (STEN), and pruning the nodes in the path before the next plan [?]. This is also known as prioritized planning and the priority order has a strong influence on the solution [?]. Time discretization may lead to conservative solutions, depending on the step size.

An alternative approach which relies only on time separation is described in the breakdown in Chapter 3. In this case, Fleet control assigns mission j to an available AGV i and finds a suitable path through the network for only one AGV i using Dijkstra or similar graph shortest path technique. Now each AGV has a list of waypoints π_i leading to its destination. A trajectory can be defined as a path π_i together with a speed profile $v_i(t)$. A set of conflict avoiding speed profiles can be found by solving the local coordination sub-problem Problem 1.

Problem 2 Given a number $N < \bar{N}$ of AGV operating on a set of assigned paths $[\pi_0, \dots, \pi_N]$, what trajectory should each one follow to allow all the missions to be completed in the minimum AGV-Time while the collision-free distance is maintained between each one at all times.

Digani et al [?] used a 2-level decomposition to solve Problem 1 as a high level zone capacitated routing problem and a local coordination sub problem within each zone. A decentralized prioritised planner based on negotiation formed a backup system. Autonomous Intersection Management (AIM) was used to reduce negotiation time of the backup system. The use of AIM leads to reduced travel time compared to negotiation based conflict resolution. The backup system ensured correct behaviour in edge cases: preventing arrivals in the same lane until the intersection was clear. This made real time control possible.

The collision avoidance constraints can be restated so they are convex, if the crossing order is fixed (FIFO order was tested). Questions remain about the importance of searching alternative crossing orders, compared to the additional computational cost. Better solution time guarantees due to a fixed order could enable AIM to operate without a backup system in more situations.

2 Aim

To compare the performance of an intersection manager with fixed First-In-First-Out (FIFO) crossing order with a published method based on a non-convex optimization with Linear objective and Quadratic constraints (*Quad_constr*), in which the crossing order can be varied to improve the objective, which is to minimize the sum of crossing time for a set number of participants. The numerical performance of the intersection manager is also important for its use as a real-time safety critical system, including the scaling with increasing numbers of approaching vehicles.

3 Hypothesis

The *Quad_constr* approach is expected to find solutions with a lower total travel time than *FIFO*. Freedom to vary the crossing order has the potential to significantly reduce total travel time in a multi-lane intersection by allowing sets of vehicles whose path do not intersect to cross the intersection together.

The *Quad_constr* approach should match *FIFO* performance if that is the best ordering, or in other cases improve upon it because it is able to search over different orderings. Both approaches make the same simplifying assumptions about the constraints, maximize the same objective by varying the arrival time at the same control waypoints.

The *Quad_constr* approach must search a non-convex space, so it is expected to take longer to solve. It is also expected to have an unpredictable solution time, which may limit the scale at which it can be applied, and possibly rule out its use as a standalone collision avoidance method at any scale. The execution time is expected to be shorter and

more consistent for the *FIFO* approach, as the linear program can be solved efficiently with interior point methods.

4 Method

4.1 Assumptions

The objective is to minimize the total travel time for all AGV to complete their missions. At this stage the missions just consist of reaching the end of their assigned path π_i .

The path π_i can be evaluated at a longitudinal distance s to find the position $\xi_i(s) = \pi_i(s)$. Using the variable s it is helpful to divide the path into three parts: approach, crossing and departing. The first part α_i approaching conflict where $s < s_{begin}$, a part traversing the conflict zone β_i where $s_{begin} < s < s_{end}$, and a part leaving the intersection γ_i where $s > s_{end}$.

A1 No external obstacles can be found on the roadmap

A2 Followers on path π_i only begin to move after the lead AGV has cleared the intersection

A3 Each AGV has a unique initial and final position

A4 The full set of paths through the intersection is known at initialization time

Assumption A1 ensures that collisions to be avoided by the motion co-ordination system are those between different AGVs. This is reasonable as most static obstacles can be avoided by construction of the roadmap. External obstacles comprise those which have unexpectedly moved since mapping time, and truly dynamic obstacles like pedestrians and human operated vehicles. For more on unexpected obstacles please refer to Chapter 2 ??.

Similarly A3 rules out unavoidable collisions (or equivalently impossible to complete missions) caused by sending two vehicles to the same place at the same time. In the decomposition described in Chapter 3 ?? this function would be the responsibility of the task scheduling module. The AGV fleet scheduling problem is not a contribution of this thesis, other works in this area include the auction based method in [?].

Assumption A2 ensures that car-following behaviour does not factor in the following analysis. In the test system arrivals were limited at the source, which counted AGVs already present on any of the associated lane alternatives, and if the lane capacity was exceeded further arrivals were stacked in a vertical queue. In Chapter 6 ?? assumption A2 is relaxed along with A3 in order to study traffic density on a link between two independently managed intersections.

Based on A4 we can compute the shape of the conflict zone. This is defined in path coordinates by the earliest intersection point with any other path s_{begin} and the latest intersection point s_{end} . As AGVs have some bodywork extending around their control point, the conflict must be expanded by the diameter of the bounding circle. In this way,

an AGV waiting outside the conflict zone can never collide with one inside. If AGV are to plan adaptive paths across the intersection, they only need to limit their variation to within the original conflict zone. This is left as further work.

4.2 Problem Representation

In general there are a number of differential constraints on the motion of an AGV along a path. Assuming the path is smooth enough to be traversed at full speed without wheel slip, lateral dynamics can be neglected without loss of generality. Methods for generating paths which are sufficiently smooth for a given traversal speed are discussed in Chapter 2 ???. Longitudinal dynamics to second order lead to a maximum speed \hat{v} and a maximum acceleration \hat{a} .

Additional assumptions B1, B2, B3 allow the optimal speed profile to be specified by the time of arrival at two waypoints. These are located at the beginning s_begin and end s_end of the conflict zone.

- B1 Waypoint timing instructions are only sent with sufficient approach distance remaining to adjust speed before reaching the first waypoint $s_begin - s > min_conflict_dist$
- B2 The conflict zone must be long enough to reach the second waypoint at the right time without violating acceleration limits $s_end - s_begin > min_conflict_dist$
- B3 All waypoints can be reached with an average speed $v < \hat{v}$

The maximum speed \hat{v} is taken from the spec sheet. The $min_conflict_dist$ parameter is calculated based on the maximum acceleration parameter \hat{a} of the AGV model. The acceleration limit is assumed to be symmetrical, so peak deceleration is $-\hat{a}$. The distance required to decelerate at \hat{a} from any valid speed $v < \hat{v}$ is given by Equation 1.

$$min_conflict_dist = \frac{v^2}{2\hat{a}} \quad (1)$$

The collision avoidance constraints can be expressed in terms of the arrival time a_i of one and the departure time d_j of the other of a pair of approaching AGV in conflict. For safe crossing between AGV i and j we require the condition in Equation 2 holds.

$$a_i > d_j \cup a_j > d_i \quad (2)$$

The only difference between the two AIM approaches is the way they transform this condition into constraints on a standard form optimization which can be solved with convex methods. One uses a fixed order leading to linear constraints and the other permits any ordering through quadratic constraints.

Both optimize over the same parameter vector ϕ as defined in Equation 3. This contains a stack of pairs of reciprocal average speeds. One for section α and one across

section β .

$$\phi = \begin{bmatrix} 1/v_{\alpha,0} \\ 1/v_{\beta,0} \\ \vdots \\ 1/v_{\alpha,0} \\ 1/v_{\beta,0} \end{bmatrix} \quad (3)$$

The constraint on approaching vehicles from those which are already past their own decision point is the same for both approaches. Every approaching AGV must have an arrival time $(s_i - s_begin_i)\phi_i$ greater than the latest departure time of any crossing vehicle d_j . Setting $t_p = \max_j d_j$ and $\mathbf{t}_p = t_p \times \mathbf{1} \in R^{(1 \times N)}$ to create N constraints from the single value of t_p this can be expressed as in Equation 4.

$$\begin{bmatrix} s_0 - s_begin_0 & 0 & \ddots & \mathbf{0} \\ \vdots & & \ddots & \vdots \\ \mathbf{0} & \ddots & s_N - s_begin_N & 0 \end{bmatrix} \phi \leq \mathbf{t}_p \quad (4)$$

4.3 FIFO

For this method the pairs in ϕ must be sorted by the remaining distance along path α before the start of the conflict $s - s_begin$. As the conflict zone extent is a fixed property of the intersection this distance will not change when other vehicles arrive on new paths, so the ordering is stable. After sorting, index $i + 1$ will be further from the decision point than index i . Then Equation 2 can be expressed as

$$\begin{bmatrix} s_0 - s_begin_0 & s_0 - s_end_0 & \ddots & \mathbf{0} \\ \vdots & & \ddots & \vdots \\ \mathbf{0} & \ddots & s_N - s_begin_N & s_N - s_end_N \end{bmatrix} \phi \leq \begin{bmatrix} a_0 \\ d_0 \\ \vdots \\ a_N \\ d_N \end{bmatrix} \quad (5)$$

Care should be taken to exclude from ϕ those AGV which have already passed the decision point defined as $s_begin - min_conflict_length$. The motion of these vehicles can no longer be altered because the on-board longitudinal controller would likely be unable to meet the new waypoint times due to physical limits on acceleration.

4.4 Quad_constr

The constraints can be expressed without imposing a fixed order by transforming the reserved time blocks into centroid α and half width β representation. This leads to Equation 6 for the constraint between any pair of AGVs (i, j) .

$$|\alpha_i - \alpha_j| > \beta_i + \beta_j \quad (6)$$

And equivalently Equation 7.

$$(\alpha_i - \alpha_j)^2 - (\beta_i + \beta_j)^2 > 0 \quad (7)$$

In terms of the parameter vector ϕ , this can be captured in a block diagonal Hessian H_{ij} , containing a block Λ_{ij} for each pair as shown in Equation 8.

$$\Lambda_{ij} = \begin{bmatrix} A_i \mathbf{1}_i \mathbf{1}_i^T A_i & -A_i \mathbf{1}_i \mathbf{1}_j^T A_j \\ A_j \mathbf{1}_j \mathbf{1}_i^T A_i & A_j \mathbf{1}_j \mathbf{1}_j^T A_j \end{bmatrix} \quad (8)$$

$$\mathbf{H}_{ij} = \begin{bmatrix} \Lambda_{ii} & \Lambda_{ij} \\ \Lambda_{ji} & \Lambda_{jj} \end{bmatrix} \quad (9)$$

The quadratic constraints are then expressed as $\phi^T \mathbf{H} \phi > \mathbf{0}$.

5 Numerical Experiment

The two intersection managers were implemented in Python with an identical messaging interface to communicate with a collection of AGV controllers with simplified dynamics.

The FIFO speeds were found with `scipy.optimize.linprog` and the vehicles ordered with the Python 3.7.6 function `sorted`

The Quad_constr speeds were found with `scipy.optimize.minimize` given the analytical Jacobian and Hessian. The speeds were converted into timed waypoints which the AGV controllers must meet as closely as possible. This conversion takes the constant speed solution for the intersection problem and retains only the safety critical part at the entry and exit of the conflict zone to pass to the AGV controllers. Vehicles with second order dynamics were also simulated.

The first test is inspired by the published results in [?], showing the improvement of intersection management similar to Quad_constr over decentralized negotiation. The tests took place on a close duplicate of three realistic intersection layouts with fixed direction lanes.

Over ten runs, one AGV was initialized at each entrance, and assigned a random exit. The clearing time $T_{clearing}$ for the last vehicle to leave the intersection is recorded in each run. The execution time to calculate the optimal waypoint times for every vehicle was calculated at the start T_{exec} . The worst delay for a single AGV compared to its free flow time to cross the intersection T_{wait} is also recorded. T_{wait} is defined somewhat differently to Digani 2019. In that paper the metric captures the time spent stationary so the optimal method has zero waiting time in every case. The waiting time is averaged over different AGV in each run, and the worst run average is recorded for that layout.

$$T_{wait} = crossing_time - \frac{PathLength}{max_speed} \quad (10)$$

In the table below T_{wait} is calculated according to Equation 10 so it is likely to be non-zero, even for optimal methods. It represents the delay caused by the intersection

compared to free flow speed. In some cases it is slightly negative, because vehicles can exceed the maximum speed to meet the waypoints given by the intersection manager.

Figure 2: Intersection 3 Layout including eight arrival nodes. Reproduced waypoints as tested shown as red dots.

6 Numerical Results

Execution time results in Figure 6 are for the *SLSQP* algorithm, running on a 1.6Ghz Intel(R) Core(TM) i5-8250U Quad Core with 16 GB main memory.

Results for two and three vehicles suggest *Quad_constr* is able to find a better solution at the cost of a higher execution time. It is difficult to establish a trend as this intersection only has three arrival nodes as shown in Figure ??.

The total travel time TTT is consistently improved by the *Quad_constr* method, and the degree of improvement is greater the busier the intersection becomes. The clearing time shows a similar trend, but there is one test where the *FIFO* solution leads to an improved $Tclearing$. As the objective function is based on Total Travel Time, the *Quad_constr* solver improves the objective with a order which leads to a worse $Tclearing$.

Comparing the $Tworst_wait$ should reveal the degree of individual sacrifice required to reach social optimum. As before, *Quad_constr* is consistently able to improve on the *FIFO* solution by choosing a different order with the benefits increasing as the

Figure 4: Intersection 4 detailed waypoints using Reeds-Shepp paths [?] to join the 66 $a - d$ pairs.

Figure 5: T_{clearing} is the time for the last vehicle to cross Intersection 4.

Figure 6: Computation time for Intersection Manager to calculate safe speeds for all participants on Intersection 4. SLSQP algorithm.

intersection gets busier. This shows that the wrong ordering leads to individual delay in higher traffic, even with a completely fair policy. Missed opportunities for non-conflicting flows to progress at the same time, lead to a longer wait for whoever crosses last.

6.1 Alternative Algorithm for Minimizing Linear Objective with Quadratic Constraints

In this test *SLSQP* stands for the Sequential Least Squares Quadratic Programming algorithm. With the default settings this algorithm terminated much faster, but the solution were lower quality as shown by the consistently worse travel time than the *trust_constr* method with $gtol = 1e^{-6}$ in Figure 17. The value of $gtol$ is the threshold the gradient of the objective must be below for termination, and has already been reduced from its default of $gtol = 1e^{-8}$ to try and speed things up.

There is a problem when $n_{agv}=8$, which leads to the number of iterations exceeding the limit, which was set to $n_{iter}=600$. This explains the very low standard deviation in Figure 19. The time taken to complete n_{iter} iterations is very consistent. Despite early termination the solution appears to meet the constraints.

The results including $n_{agv}=9,10,11$ show a different pattern. Suggesting *slsqp* fails to find a good solution here. The execution time levels off as the solutions become much worse, suggesting the search terminated early. The iteration limit was not reached.

It is surprising the execution time for FIFO method which involves solving a linear program is so high, approaching a second for only 11 AGV. Closer inspection reveals

Figure 7: Average Clearing Time over 10 runs with random paths drawn from the six options.

Figure 8: Total Simulated Travel Time in AGV-Time units

that 99% of this time is spent sorting the list before the linear program is executed which seems to indicate a sorting bug.
